ABSTRACT

Organ-specific in vitro toxicity assays are often highly sensitive, but they lack specificity. We evaluated here examples of assay features that can affect test specificity, and some general procedures are suggested on how positive hits in complex biological assays may be defined. Differentiating human LUHMES cells were used as potential model for developmental neurotoxicity testing. Forty candidate toxicants were screened, and several hits were obtained and confirmed. Although the cells had a definitive neuronal phenotype, the use of a general cell death endpoint in these cultures did not allow specific identification of neurotoxicants. As alternative approach, neurite growth was measured as an organ-specific functional endpoint. We found that neurite extension of developing LUHMES was specifically inhibited by diverse compounds such as colchicine, vincristine, narciclasine, rotenone, cycloheximide or diquat. These compounds reduced neurite growth at concentrations that did not compromise cell viability, and neurite growth was affected more potently than the integrity of developed neurites of mature neurons. A ratio of the EC50 values of neurite growth inhibition and cell death of > 4 provided a robust classifier for compounds associated with a developmental neurotoxic hazard. Screening of unspecific toxicants in the test system always yielded ratios < 4. The assay identified also compounds that accelerated neurite growth, such as the rho kinase pathway modifiers blebbistatin or thiazovivin. The negative effects of colchicine or rotenone were completely inhibited by a rho kinase inhibitor. In summary, we suggest that assays using functional endpoints (neurite growth) can specifically identify and characterize (developmental) neurotoxicants.
INTRODUCTION

Toxicological test systems do not only require initial conceptualization and basic description, as in other fields of science. They also necessitate detailed further development and a lengthy evaluation process. In some domains, such as cosmetics or drug testing, or in the pre-selection of environmental toxicants for more extensive testing, assays may be used without formal validation, if there is sufficient evidence for their scientific validity. Some regulatory authorities, as well as open platforms such as the evidence-based toxicology (EBT) consortium, provide guidance on method evaluation (Griesinger et al. 2009; Hartung 2010). For instance, documents have been produced on good cell culture practice (GCCP) (Hartung et al. 2002), on guidelines for data presentation (Leist et al. 2010) and assay reliability (Schneider et al. 2009), on how to establish a test system for developmental neurotoxicity (DNT) and on how to select compounds for DNT testing (Kadereit et al. 2012; Kuegler et al. 2010; Zimmer et al. 2011). However, until now only few test systems in the field of neurotoxicity and developmental neurotoxicity have been developed further on the basis of such guidance documents (Bal-Price et al. 2012; Fritsche et al. 2011). More of this type of work is necessary, as it has recently been noted that several published studies are necessary for an evaluation of a method according to criteria of evidence-based toxicology (Judson et al. 2013; Stephens et al. 2013).

DNT often manifests itself in functional disturbances, that may appear hard to model in vitro (van Thriel et al. 2011). However, it is widely assumed (Bal-Price et al. 2012; Hogberg et al. 2009; Kadereit et al. 2012) that DNT is ultimately the consequence of the disturbance of relatively basic biological processes, such as differentiation, proliferation, migration and neurite growth. Therefore several in vitro systems have been established that test the disturbance of such biological activities by chemicals (Balmer et al. 2012; Frimat et al. 2010; Harrill et al. 2011b; Radio et al. 2008; Zimmer et al. 2012). One endpoint that has found a lot
of attention is neurite outgrowth (Radio and Mundy 2008). This activity is required during the formation of the nervous system for the development of dendrites and axons, and it is a precondition for synaptogenesis and cell connectivity. Different neuronal cell lines of human or rodent origin can be used to study neurite outgrowth and to measure disturbances after exposure to toxicants (Harrill et al. 2011a). A particular challenge for development of neurite outgrowth assays is the evaluation of test system predictivity by comparison to in vivo data. As alternative, it has been suggested to focus more on data quality, and on a broad evaluation of the biological basis of the test and its mechanistic consistency under many different situations and types of challenge (Leist et al. 2012).

From animal studies, it is known that chemicals can affect neurite growth in different ways. For instance, in utero cocaine exposure reduced the total length of neurites in the locus coeruleus of rats (Snow et al. 2001). The pesticide diazinon impaired neurite outgrowth in the forebrain and brainstem of rats, exposed to the chemical on postnatal day 1-4 (Slotkin et al. 2006). Inhibited neurite formation was also observed after exposure of 7-day-old rat pups to ethanol (Joshi et al. 2006). In contrast, accelerated growth was observed, e.g. after treatment with the rho kinase (ROCK) inhibitor Y-27632 which enhanced the sprouting of corticospinal tract (CST) fibers after CST lesion in adult rats (Fournier et al. 2003).

Also in humans, disturbed neurite growth is one of the assumed reasons for disorders of neural development such as autism spectrum disorders (ASD). In adults with ASD, decreased axonal length has been observed post mortem in the anterior cingulate cortex (Zikopoulos and Barbas 2010). Moreover, numerous ASD candidate genes are linked to neurite outgrowth and neurite guidance (Hussman et al. 2011).

The number of in vivo studies analyzing the altered growth of neurites under toxicant stress is limited. It is still a technical challenge to visualize neurites in the developing or mature brain and to measure changes in the growth rate. New technologies for estimating neurite density in
*vivo* (Vestergaard-Poulsen et al. 2011; Zhang et al. 2012) are currently under development but their application for investigating neurite toxicity *in vivo* still needs to be refined. A few studies make use of certain anatomical situations more suitable for analysis. From these, we know that PCBs can affect dendrite growth of dorsal root ganglion (DRG) neurons (Yang et al. 2009), and that different stress conditions affect dendrites in the hippocampus (McEwen 1999). Moreover, it is generally known that hypothyroidism during brain development affects neurite connections (Barakat-Walter et al. 2000). Apart from these pioneering neurodevelopmental studies, there is a large body of evidence, that developed neurites are particularly sensitive targets of chemical toxicity. A large fraction of known neurotoxicants specifically targets neurites (Spencer et al. 2000). In such cases, specific neurite degeneration is often occurring independent of cell death. Prominent examples are chemotherapy-induced neuropathies (Quasthoff and Hartung 2002) after treatment with platinum compounds or alkaloids such as colchicine or vincristine. Another chemical class known to induce axonal neuropathy are acrylamide and related structures (LoPachin et al. 2002). The above findings suggest that neurites, developed or growing, play an important role in neurons. Therefore, there is a high need for human cell-based test systems that would provide data faster and easier than the hitherto used animal models.

Several test systems have already been developed successfully to assess neurite outgrowth in low density cultures (Harrill et al. 2010; Mitchell et al. 2007; Radio et al. 2008; Ramm et al. 2003; Yeyeodu et al. 2010), whereas the number of reports based on more interconnected high-density cultures is quite low (Narro et al. 2007; Stiegler et al. 2011; Wang et al. 2010), mainly due to the difficulties with assigning a specific neurite to a defined cell. A particular challenge for toxicological test systems for neurite growth is the definition of specificity of the observed effect for neurite growth. Identification of such compound features requires that generally cytotoxic effects are distinguished from effects of chemicals that are specifically affecting neurite growth, but not overall cell survival. In the present study, we made use of a
human cell-based high-density neuronal test system (Stiegler et al. 2011) to further explore the usefulness of simultaneous measurements of viability and neurite growth to define assay specificity. For this purpose, the system was challenged with a broad range of chemicals, including a high number of generally cytotoxic compounds. The dataset generated with the unspecific toxicants was found to be instrumental for the evaluation of assay performance with respect to the generation of false positives, and for the identification of interesting true positive hits. The second goal of the study was to provide data on the performance characteristics and consistency of the assay under different types of challenge. For instance, we compared the toxicity of chemicals to developing vs. developed neurites, to answer the question whether a compound specifically inhibited the outgrowth of neurites. We also challenged the test system with groups of mechanistically, but not chemically, related compounds. The mechanistic consistency of the assay was further explored by exposing the test system to compound mixtures expected to behave additively or antagonistically.
Materials and Methods

Materials and chemicals

Acrylamide, antimycin A, acetylsalicylic acid, blebbistatin, brefeldin A, buthionine sulfoximine (BSO), calcein-AM, carbonyl-cyanide-3-chlorophenylhydrazone (CCCP), chlorpyrifos, cisplatin, colchicine, cycloheximide, cytochalasin B, dibutyryl-cAMP (cAMP), 2,4-dinitrophenol, diquat dibromide, etoposide, fibronectin, fipronil, flavopiridol, hoechst bisbenzimide H-33342, honokiol, IPA3, potassium chromate (K$_2$CrO$_4$), mannitol, menadione, methylmercury (II) chloride (MeHg), mevastatin, nacilasine, nocodazole, oligomycin, paraquat dichloride, puromycin, resazurin sodium salt, rotenone, saponin, sodium orthovanadate (Na$_3$VO$_4$), SP600125, tert-butyl hydroperoxide (tBuOOH), tetracycline and vincristine were from Sigma (Steinheim, Germany).

Recombinant human FGF-2 and recombinant human GDNF were from R&D Systems (Minneapolis). Bisindolylmaleimide I (Bis1), dimethyl sulfoxide (DMSO), 1H-[1,2,4]oxadiazolo[4,3-α]quinoxalin-1-one (ODQ), okadaic acid potassium salt, PTP inhibitor IV, H1152, simvastatin and U0126 were from Calbiochem (Darmstadt, Germany). Y-27632 was from Tocris Bioscience (Bristol, UK), tween-20 and sodium dodecyl sulfate (SDS) were from Roth (Karlsruhe, Germany), HA-1077 from Ascent scientific (Cambridge, UK), thiazovivin from Selleck (Munich, Germany), chlorpyrifos oxon from Chem. Service inc. (West Chester, USA), piericidin from Enzo life science (Lörrach, Germany) and methamphetamine was obtained from Lipomed (Arlesheim, Switzerland). All culture reagents were from Gibco unless otherwise specified.

Cell culture

Handling of LUHMES human neuronal precursor cells was performed as previously described in detail (Lotharius et al. 2005; Schildknecht et al. 2009; Scholz et al. 2011). Briefly
maintenance of LUHMES cells was performed in proliferation medium, consisting of advanced DMEM/F12 containing 2 mM L-glutamine, 1 x N2 supplement (Invitrogen), and 40 ng/ml FGF-2 in a 5% CO₂/95% air atmosphere at 37° C. LUHMES cells were passaged every other day and kept until passage 20. For differentiation 8 million cells were seeded in a Nunclon T175 in proliferation medium for 24 h. The next day medium was changed to differentiation medium (DM II), consisting of advanced DMEM/F12 supplemented with 2 mM L-glutamine, 1 x N2, 2.25 µM tetracycline, 1 mM dibutyryl 3',5'-cyclic adenosine monophosphate (cAMP) and 2 ng/ml recombinant human glial cell derived neurotrophic factor (GDNF). 48 h later cells were trypsinised, and seeded in a density of 100,000 cells/cm² on dishes precoated with 50 µg/ml poly-L-ornithine (PLO) and 1 µg/ml fibronectin in advanced DMEM/F12 containing 2 mM L-glutamine, 1 x N2 and 2.25 µM tetracycline but without cAMP and GDNF (DM).

**Standard experimental setup**

To detect effects on neurite growth, cells were seeded at a density of 30,000 cells per well in 50 µl DM on PLO/fibronectin coated 96-well dishes. Compounds were serially diluted in DM, and 50 µl were added to the cells 1 h after seeding. Analyses were performed 24 h after initiation of the treatment. To detect effects on neurite degeneration cells were seeded at the same density in 100 µl DM. At day 5 (d5) DM was removed and 100 µl of fresh DM with serially diluted compounds were added. Analyses were performed 24 h or 72 h later. The maximum DMSO concentration used was 0.33% and had no influence on cell viability or neurite growth.

**Resazurin measurement**

Cell metabolic activity was detected by a resazurin assay (Schildknecht et al. 2009). Briefly, 10 µl resazurin solution were added to the cell culture medium to obtain a final concentration of 10 µg/ml. After incubation for 30 min at 37° C, the fluorescence signal was measured at an
excitation wavelength of 530 nm, using a 590 nm long-pass filter to record the emission. Fluorescence values were normalized by setting fluorescence values of untreated wells as 100% and the values from wells containing less than 5% calcein-positive cells as 0%.

Quantification of neurite outgrowth

Neurite growth was detected as previously described in detail (Stiegler et al. 2011). Briefly, cells were stained with 1 µM calcein-AM and 1 µg/ml H-33342 for 30 min at 37° C. An Array-Scan VTI HCS Reader (Cellomics, PA) equipped with a Hamamatsu ORCA-ER camera was used for image acquisition. Ten fields per well were imaged in two channels using a 20x objective (2 x 2 pixel binning). Excitation/emission wavelengths of 365 ± 50/535 ± 45 were used to detect H-33342 in channel 1 and 474 ± 40/535 ± 45 to detect the calcein signal in channel 2.

Nuclei were identified as objects in channel 1 according to their size, area, shape, and intensity. The nuclear outlines were expanded by 3.2 µm in each direction, to define a virtual cell soma area (VCSA) which was bigger than the average cell size to reduce false positive neurite areas. All calcein-positive pixels of the field were defined as viable cellular structures (VCSs). In an automatic calculation, the VCSAs, defined in the H-33342 channel, were used as filter in the calcein channel and subtracted from the VCS. The remaining pixels (VCS - VCSA) in the calcein channel were defined as neurite area.

Statistics and data mining

Data are presented, and statistical differences were tested by ANOVA with post-hoc tests as appropriate, using GraphPad Prism 5.0 (Graphpad Software, La Jolla, USA).
Results and Discussion

Conditions and acceptance criteria for the use of neurite growth as test endpoint

LUHMES cells can be differentiated by addition of tetracycline within 5 days to mature neurons, as evaluated by the expression of neuronal markers, by changes of their morphology, and by measurements of electrical activity (Scholz et al. 2011). It has been shown earlier that the cells start expanding their neurites on day 2 (d2) and that quantification of the overall neurite area at day 3 (d3) is a suitable measure of initial neurite growth (Stiegler et al. 2011). After 4-5 days, this growth is saturated, and a ‘mature’ neurite network of relatively constant size is established (Scholz et al. 2011). We used these characteristics here for two different test protocols: exposure to chemicals from d2-d3, and measurement on d3 as parameter to assess ‘neurite growth’, and exposure to chemicals from day 5 (d5) – day 6 (d6), and measurement on d6 as parameter to assess ‘neurite toxicity’ (Fig. 1a). In a first, rough approximation, these two measures were assumed to reflect developmental neurotoxicity (prevention of neurite formation) vs neurotoxicity, i.e. damaging effects of compounds to already developed neurites. We are aware of the fact that such a strict classification represents a strong simplification of reality. Nevertheless, we assume that comparison of the two assays helps to identify compounds that act by inhibiting the growth (development) of neurites without having adverse effects on established neurite structures as such.

The hazardous effect of chemotherapeutic alkaloids such as colchicine, vincristine or of nocodazole, on neurites is well-established. These microtubule disruptors do not only interfere with the microtubule organization during cell division, but also with the extension of microtubules during axonal growth (Daniels 1972; Fontaine-Lenoir et al. 2006; Geldof et al. 1998). They were therefore considered here as a potential positive control to illustrate the assay algorithm. The measurement of neurite area is based on a life-cell staining of the total
cell cytoplasm with calcein, and imaging of the result on an automated microscope. The algorithm identifies then all live structures not belonging to a cell body as viable neurites, as illustrated in (Fig. 1b). The example images of colchicine (5 nM) effects demonstrate clearly that the compound reduced the neurite area, while the cell bodies were all still viable. An important feature of the assay is that it allows for a simultaneous quantification of viable cells (calcein positive cells) out of the total cell number (all Hoechst33342- stained nuclei) and the assessment of neurite growth (Fig. 1b).

Three microtubule inhibitors, that are structurally diverse, and that show different affinities for tubulin, were used to test the sensitivity and reproducibility of the test system. Colchicine, nocodazole and vincristine were tested over a large concentration range in three different cell preparations. The data showed reproducibly an inhibition of neurite growth and a potency ranking that corresponded to the ranking of tubulin affinities (Correia and Lobert 2001) (Fig. 1c). A key question is, whether these neurite data can be used as such for the identification of developmental toxicants and/or their ranking in our assay system. Can compounds such as colchicine and vincristine really be considered developmental toxicants on the basis of such neurite growth data? We felt that such an interpretation would produce too many false positives, and that additional criteria would be required to increase the specificity of the assay. This was examined from different angles in the following experiments.

The main confounding factor of neurite growth tests may be effects of compounds on overall cell survival (named here: general viability). For instance, simple detergents (not assumed to be developmental toxicants or neurite toxicants) may produce similar neurite area curves as the apparently specific microtubule inhibitors. For this reason, we assessed two general viability endpoints in all experiments in the same wells used for neurite evaluation: the relative number (= percentage) of viable cells and the capacity to reduce resazurin to resorufin. Colchicine was chosen again for an exemplary display. The comparison of all endpoints at many concentrations of the test compound showed that neurite growth is affected at much lower concentrations than the general viability. The EC20 for the neurite area was 1.9
nM and for viable cells it was 10 nM (resulting in a ratio > 5). The EC50 of the neurite area was 4 nM and the viability was still 100% at that concentration (Fig. 1d). A reduction of neurite growth by 50%, without reduction of viability was also found for nocodazole and vincristine (Suppl. Fig. 1a, b). Thus, on the basis of this complete set of data, all the three microtubule inhibitors can be considered as developmental neurotoxicants affecting neurite outgrowth.

To further explore the relationship of neurite growth and cytotoxicity, we chose a small set of diverse compounds for further testing. Etoposide, a topoisomerase inhibitor anti-cancer drug and buthionine sulfoximine (BSO), a metabolic inhibitor of glutathione synthesis, were chosen as chemicals supposed not to interfere with neurites. Both compounds reduced neurite growth to a significant extent compared to untreated control cells, and the curve shape of neurite area did not look much different from that found for the microtubule inhibitors. When the ‘apparent neurite growth inhibition’ was compared with the reduction of viability, it became evident that the concentration dependencies for both endpoints were the same (Fig. 2a, b). This was not an averaging effect due to the combination of results from different test runs, but it was observed in each of at least three independent experiments (Suppl. Fig 1c, d). The same data as for ‘viable cells’ were also found with the resazurin assay. In fact, the two tests were used for all experiments in this work, but as the results did not significantly differ, only one of the endpoints is indicated in most figures. We interpret the findings with BSO and etoposide in a way that ‘apparently inhibited neurite growth’ is a secondary consequence of reduced viability, and we suggest classifying such compounds as ‘unspecific toxicants’.

This concept has a technical and a conceptual implication. Technically speaking, unspecific toxicants are neither classical negative (having no effect on the endpoints of the test system) nor positive hits (showing a specific effect). They form a group of their own. Conceptually, such compounds have to be interpreted as negative, i.e. as not affecting neurite growth in any specific way. As this may lead to misunderstandings, it requires some further specification: such a negative statement does not imply that a compound is not a developmental toxicant. It
only implies that positive evidence for such an activity cannot be found in this assay system. There is no way to determine whether (a) the compound directly inhibits neurite growth, and in parallel also reduces viability in this particular cell culture system, or whether (b) it primarily reduces viability, and that reduced neurite growth is found because of ongoing cell death. In simple terms, the neurite data cannot be interpreted in a meaningful way, when they are associated with ongoing cell death. As in all test systems, the increase of specificity (by including comparison to viability) is accompanied by a decrease in sensitivity (inability to classify compounds as developmentally neurotoxic, when they affect cell viability). An example illustrates how changes in the test system may alter sensitivity: theoretically, cells of another system may be more robust, and tolerate concentrations of e.g. 2 µM etoposide without loss of viability. If neurite growth inhibition in those other cells would be seen at the same concentration as in LUHMES cells (50% at 2 µM), this other test system would allow the detection of a developmental neurotoxicity potential of etoposide that is masked in the LUHMES model by parallel cytotoxicity.

Testing of two further compounds with supposed effects on neurites indicated the need for some quantitative definition of specificity criteria to define a positive test result. Cycloheximide, an inhibitor of protein biosynthesis with strong effects on peripheral neurites (Gilley and Coleman 2010), reduced neurite growth significantly at concentrations at which no effect on viability was observed (Fig. 2c). There was a large ratio of the two endpoints of the EC20 values and EC50 values. However, the EC50 for general viability was not reached at testable compound concentrations. For ratio formation, we therefore introduced the rule that in this case the highest concentration tested would be used for further calculations. Paraquat is a pesticide with potential toxicity for dopaminergic neurons (McCormack et al. 2002) and it affected neurite growth of LUHMES more potently than general viability (Fig. 2d). However, we observed some cytotoxicity at all concentrations associated with strongly reduced neurite growth. This is admittedly a case that may be classified as positive (specific developmental neurotoxicant) or negative (unspecific toxicant) depending on the rules of the
assay interpretation model. We decided here to focus mainly on the horizontal shift of the
curves as anchor point for interpretations of the LUHMES assay. This criterion may need to
be adapted as more information on the underlying mechanisms becomes available. The
general usefulness for screen purposes was explored in the following with a large number (> 30) of compounds suspected to affect neurites.

**Classification of substances as specific neurite growth inhibitors**

To define thresholds of assay specificity, we used unspecific toxicants. Nine compounds were
chosen according to the following rules: (a) they are not known to affect neurite growth, (b)
their known mode of action and their chemical properties make it unlikely that they
specifically affect the biology of neurite growth. The selected chemicals were the glutathione
synthesis inhibitor buthionine sulfoximine (BSO), the mitochondrial uncouplers CCCP and
2,4-DNP, the detergents SDS and tween-20, the heavy metal ion K$_2$CrO$_4$, the DNA-
interacting compounds etoposide and H-33352 and the oxidant tertiary butyl-hydroperoxide
(tBuOOH). This set of chemicals was used as ‘unspecific controls’, i.e. to define non-specific
outcomes of the neurite growth inhibition assay. For this purpose, we determined their EC50
values for neurite growth inhibition and for reduction of general viability, and the ratio of
these EC50 values was calculated for each experiment and each compound. The average ±
standard deviation (SD) of all these ratios was 1.4 ± 0.83, i.e. neurites were on average
affected by unspecific compounds at slightly lower concentrations than general viability. For
defining criteria for ‘positive responses’ we used a rule commonly used for many analytical
methods as guidance: we assumed that significant effects (of specific compounds) should be 3
SD away from the baseline (average of unspecific compounds). Thus, we defined a ratio of 4
as threshold/acceptance criterion for compounds we regarded as positive hits of the screen
(Fig. 3). Typical positive controls known from previous studies (U0126, flavopiridol,
brefeldin A, bisindolylmaleimide I and sodium orthovanadate (Na$_3$VO$_4$) (Harrill et al. 2010;
Radio et al. 2008; Radio and Mundy 2008; Stiegler et al. 2011) had EC50 ratios far above 4.
Compounds with an EC50 ratio < 4 were defined as negative. This rule is the pivotal basis for conferring specificity to the assay, even though it may reduce its sensitivity. A negative classification in our assay means that there is no positive evidence for a neurite growth inhibition. It is not evidence of absence of such a property.

Using these criteria, we screened substances, that we found likely to affect neurite growth because of their assumed primary mode of action or because of reports in the literature (Fig. 3, Suppl. Fig. 2). The tested compounds comprised many biological activity groups like cytostatic drugs (cisplatin), redox cyclers/pesticides (paraquat, diquat), mitochondrial toxins (rotenone, antimycin A, oligomycin, piericidin), cytoskeleton toxicants (colchicine, okadaic acid, nocodazole, vincristine), acetylcholine-esterase inhibitors (chlorpyrifos, chlorpyrifos-oxon) and other substances like the neurotoxin acrylamide, the guanylylcyclase inhibitor ODQ, the antipsychotic and possible teratogenic drug haloperidol, the stress kinase inhibitor SP600125, the HMG-CoA reductase inhibitors simvastatin and mevastatin, an inhibitor of protein tyrosine phosphatases PTP IV, the RhoA activator narciclasine, a group of rho kinase (ROCK) inhibitors (H-1152, HA-1077, thiazovivin) and the myosin II inhibitor blebbistatin.

The tested microtubule inhibitors colchicine, nocodazole and vincristine were classified as neurite growth specific toxicants. In the group of tested pesticides consisting of rotenone, paraquat, diquat, chlorpyrifos and chlorpyrifos-oxon, a clear positive effect was determined for rotenone, paraquat and diquat. Another group of compounds influencing neurite growth were Rho/ROCK pathway modifiers. Some of them accelerated the neurite growth, instead of inhibiting it.

The ratio of the EC50 values of neurite growth versus viability proved to be a useful classifier for compounds associated with a developmental neurotoxic hazard. The results shown here are based on average EC50 values derived from three biological replicates (independent experiments).

For more extensive screens, a more simplified procedure is desirable. Therefore, we examined how the classification would have looked like for individual experiments. Also the data points
of the positive compounds from individual experiments all fell within the ‘specific area’ of the scatter plot (Suppl. Fig. 2). The approach taken here is firmly established in the field of biomolecular screening, as performed in pharmaceutical industry, but it differs from the traditional reporting of in vitro test systems in toxicology. The more traditional approach in this field is based on statistical evaluation of a compound effect vs. a negative control. The specificity definition we have chosen here is easily adaptable to other situations, including simpler assays with a single endpoint. Measures based in some way on the variation/confidence limits of the reference group can always provide a useful tool to classify further tested compounds: either the compounds are within the ‘noise limit’ (negative classification), or outside the background noise (specific hits). In the LUHMES test system we newly identified 7 specific neurite growth inhibitors (rotenone, narciclasine, colchicine, vincristine, nocodazole, paraquat, diquat) and 4 neurite growth accelerators (H1152, HA-1077, thiazovivin, blebbistatin). These results will be displayed and discussed in greater detail in the following sections.

**Specific effects of rotenone, but not other respiratory chain toxins**

Rotenone, a complex I inhibitor of the mitochondrial respiratory chain, inhibited neurite growth significantly at 0.1 µM (Fig. 4a, green solid line), whereas viability was affected only at ten times higher concentrations. This was initially surprising. To identify potential artefacts, the original images of the high-content screen were retrieved and evaluated by trained observers. The effect was fully confirmed, and representative example images show clearly that neurite area was reduced by low concentrations of rotenone, while the number of viable cells per field was not affected. Only at higher concentrations, a concentration-dependent decrease in cell number was observed, and all viable cells were completely devoid of neurites (Fig. 4b). This big difference of effects on neurite growth and viability was observed in four independent experiments (Fig. 4c). To follow up on this positive hit we asked the question whether rotenone targets neurites in general or whether it specifically influences their growth.
Therefore we compared the effects of rotenone (24 h exposure in both cases) on differentiating LUHMES on day 2 (d2) with its effects on mature cells with a fully differentiated neurite network on day 5 (d5) (Fig. 4a, green dashed line). The mature neurites were less sensitive to rotenone. In fact the concentration-dependency of the neurite degeneration was not significantly different from the one for general viability, when mature neurons were used as model system (Fig. 4a, orange dashed line). The general cytotoxicity of rotenone was the same for d2 and d5 cells (Fig. 4a viability for d5, Fig. 4c viability for d2), and only the sensitivity of the neurites was different. Thus, rotenone is an example for a compound with a higher toxic potency for the developing neurons than for the developed cells. This effect was unique for rotenone, as we found no other mitochondrial toxicant with such an effect on neurites. Complex I inhibitor piericidin, complex V inhibitor oligomycin (Fig. 4d) as well as the uncouplers of oxidative phosphorylation CCCP or 2,4-DNP had no impact on neurites at several tested concentrations. For the complex III inhibitor antimycin A we identified concentrations (25-50 µM) at which neurites were significantly more affected than viability. But the EC50 ratio of viability to neurite area was only 1.6 (Fig. 4d), whereas rotenone showed a ratio > 15. According to our rules, antimycin A was classified as negative.

Other reports, using rodent cells (PC 12 cells, primary hippocampal neurons), also suggest that rotenone has some specific effect on axon formation (Sai et al. 2008; Sanchez et al. 2007). The mechanism is unknown, but it has been suggested that complex I inhibitory parkinsonian toxicants may affect dopaminergic neurons by microtubule depolymerization (Ren et al. 2005). Other processes which are also dependent on correct microtubule formation like migration and proliferation have also been shown to be inhibited by rotenone in mesencephalic neural stem cells (Ishido and Suzuki 2010). The process of microtubule formation is indeed crucial for the growth of axons as suggested for instance by our findings on colchicine and related compounds. To identify the underlying mechanisms of rotenone’s developmental neurotoxicity more clearly, in depth experiments and additional technical approaches are needed. As neurons can tolerate a partial depletion of ATP for long times, if
secondary apoptotic processes are blocked (Polzl et al. 2012; Volbracht et al. 1999), a specific, cell death independent action of rotenone on young developing neurons seems likely.

**Differential chemical effects on neurite growth vs. neurite stability**

Our observation that rotenone specifically targets neurite growth (d2 cells), as compared to neurite stability (d5 cells), suggests that such a distinction may be used more generally to define the specificity of an assay (or a compound) for neurite growth inhibition. For this purpose, we tested a group of eleven compounds, which had been classified as specific neurite toxicants in the d2\rightarrow d3 neurite growth assay, on neurite degeneration (d5\rightarrow d6) (Fig. 1a). Concentration-response curves were obtained for effects on the neurite area and general viability for d5 cells treated for 24 h. Scatter plots of the effects on EC50 (general viability) vs. EC50 (neurite area) measured on d3 (Fig. 5a) or d6 (Fig. 5b) showed that most compounds did not affect the mature neurites in a specific way (without killing the cells). Nine of the eleven compounds were located on the dashed line, indicating identical EC50 values for both endpoints at d6.

The data obtained in these experiments also allowed to answer the question, whether the EC50 values for neurites or for general viability were shifted in absolute terms between d3 and d6 cells. Seven of the compounds were much more potent on developing neurites, than on developed neurites, and the average of the ratios of EC50 (neurites d6)/EC50 (neurites d3) was 11.4. This means that the functional endpoint of neurite growth is more sensitive towards toxicant exposure (Fig. 5c and Suppl. Fig. 3a). To test whether developing cells are in general more sensitive to toxicant exposure than mature cells, we compared the EC50 values of resazurin reduction. The ratio of this endpoint for the two developmental stages of d6 to d3 is 0.74. This suggests that the general cytotoxicity is independent of the developmental stage of the cells, and that the younger cells are not less robust than adult cells (Fig. 5c and Suppl. Fig. 3b).
The above data suggest indirectly, that general cytotoxicity data are no good predictor for neurotoxicity, even though they are obtained from neuronal cultures. To examine this point in more detail we selected a subgroup of our test compounds. They comprised neurotoxicants such as MnCl$_2$, acrylamide and trimethyltin chloride, as well as neurite growth inhibitors and non-neurotoxicants for which literature values could be found in the Halle registry of cytotoxicity data (Halle 2003). Resazurin reduction of d3 (Suppl. Fig. 4a) and of d6 cells (Suppl. Fig. 4b) was plotted against the data from the Halle registry, which are based on average cytotoxicity tests on several non-neuronal human cell lines such as HeLa and HEK293. The LUHMES cytotoxicity data and the Halle registry values correlated to about 85%. This means that the cytotoxicity of compounds determined in young or mature LUHMES as test system correlates to a high degree with that observed in other human cell lines of non-neuronal origin. This corroborates our assumption that human neurotoxicity cannot be determined by cytotoxicity measurements in human neuronal cell cultures, and that only a specific functional assay, such as neurite growth, yields specific results. Observations pointing into a similar direction were also made in other model systems (Gartlon et al. 2006).

**Independence of key findings from data processing algorithm**

Our concept of whole curve comparisons does not allow statements on individual concentrations of a given compound. Therefore, we were interested how individual test conditions (defined concentrations of defined compounds) would distribute in a scatter plot that correlates effects on neurites with those on general viability. We produced a scatter plot of the individual data points for each concentration of a test compound, so that inhibition of neurite growth and the general cytotoxicity were used as coordinates. The data were plotted for three groups of compounds: negative controls, unspecific controls and eight neurite growth inhibitors (Fig. 6). Negative controls were mannitol and acetylsalicylic acid. They did not affect any endpoint, even though concentrations up to 4 mM for mannitol and 2 mM for acetylsalicylic acid were chosen (Fig. 6, green dots). Unspecific compounds, like SDS, BSO,
etoposide, oligomycin, tBuOOH, affected neurite growth and viability to a more or less similar extent at all tested concentrations (Fig. 6, black dots). More detailed analysis shows, that for such compounds concentrations exist, at which they reduce general cell viability significantly (by 30-60%), but neurite area is reduced much more (by up to 35% more). Antimycin A, mentioned in the paragraph above (Fig. 4d) is also such a compound. It is important for the understanding of our test approach that the specificity rule we used here classifies such substances as negative. The compounds classified as specific inhibitors of neurite growth localized differently in the scatter plot: there were always data points that showed a clear impact on neurites, with no major influence on viability (Fig. 6, blue dots). This way of data evaluation (based on different principles than the EC50 ratios) could form an alternative basis for a specificity rule. It appears to be useful as an option for smaller screens. Notably, the newly identified neurite growth inhibitors found in our screen would also have been detected based on these alternative criteria.

As a further control, we also examined, whether other methods to quantify neurite effects would lead to similar results. For this purpose, we counted the percentage of cells with or without neurites for several representative experimental conditions, and using the same images that had been used for the automated neurite area quantification algorithm. The neurite area endpoint correlated well with the number of cells with neurites obtained by manual counting (Fig. 7). A smaller number of conditions was also used for automated counting of neurite-containing cells, based on specifically-developed software (Schoenenberger et al. 2012). Also in this case, the endpoints correlated well. We conclude from these comparisons, that the toxicological effects we observed for neurite growth inhibitors in the LUHMES assay (as presented here) are robust, and can be detected by different analytical methods as well.

**Detection of compounds that increase the neurite area**

An important parameter for each assay is its dynamic range. A particular question is, whether deviations from normal can be measured into both directions, and which types of positive
controls can be used. The compound Y-27632 has been known to affect LUHMES neurite growth positively (Stiegler et al. 2011). These findings, and other literature data (Fuentes et al. 2008; Kubo et al. 2008; Nikolic 2002) pointed to a role of the ROCK pathway in the control of neurite growth. The pathway is triggered by the activated RhoGTPase RhoA that binds to the rho kinase (ROCK), and activates it thereby. ROCK phosphorylates myosin light chain (MLC), and this results in the induction of actin-activated non-muscle myosin II ATPase. The downstream consequences are a local collapse of the neuritic growth cone and induction of stress fibers (Kubo et al. 2008). An inhibition of this pathway would therefore lead to an accelerated neurite growth due to less stress fiber formation and a reduced tendency of growth cone collapse. The role of this signalling cascade for our test system was explored further by the use of different compounds that affect this pathway. We found that the different ROCK inhibitors H1152, HA-1077 and thiazovivin as well as the myosin II inhibitor blebbistatin accelerated neurite growth significantly (Fig. 8a, c-e). The area of the culture dish covered with neurites was increased by up to 80% (with inhibitor HA-1077). When the same compounds were used on d5 LUHMES no measurable effect was observed (data not shown). Inhibition of the ROCK pathway therefore seems to have a particularly prominent role in the growth process of neurites. Whether compounds leading to accelerated neurite growth should be interpreted as toxicants is an open issue and should be the subject of further investigations. In regenerative medicine, and in adults, accelerated outgrowth or preservation of neurites would rather be considered beneficial (Hansson et al. 2000; Schierle et al. 1999; Volbracht et al. 2001; Volbracht et al. 1999; Volbracht et al. 2006). There is, however, some published evidence that uncontrolled elongation of neurites during development may be related to neurotoxicity: hypertrophic dendritic outgrowth has been observed in parts of the embryonic prefrontal cortex after cocaine had been administered to pregnant rabbits at gestational stages (Jones et al. 2000; Stanwood et al. 2001).

We also investigated potentially toxic effects of the ROCK pathway activation. Narciclasine, which greatly increases Rho A’s activity (Lefranc et al. 2009), strongly decreased neurite
growth (Fig. 8b, e). These data underline the mechanistic consistency of the assay, as the achieved results were as expected considering the interference of these compounds with the ROCK pathway. The fact, that we can detect accelerating as well as inhibitory effects on neurite growth gives evidence of the broad dynamic range of our growth assay. Possibly the test system may also be used for pharmacological questions, e.g. for identification of compounds that facilitate neuroregeneration by accelerating neurite growth.

**Biological effects of combinations of substances**

In the last step of the assay evaluation, we tested the effect of combinations of compounds. Consistent responses of the test system to at least binary mixtures would indicate its usefulness for more mechanistic questions and for exploring toxicity intervention. Moreover, we hoped to find additional evidence for the specificity of the hits discovered in our initial screen (Fig. 3). In a first set of experiments, we replicated earlier findings on the combination of the two kinase inhibitors bisindolylmaleimide I (Bis1) and U0126 (Stiegler et al. 2011). At certain drug concentrations, the neurite area could nearly be reduced to zero, without a significant reduction of cell viability. Moreover, three entirely independent experiments with the combination of two chemicals gave consistent results (Fig. 9a). We interpret this as indication for a high reproducibility and robustness of the test system.

A recent pilot study (Stiegler et al. 2011) indicated that the ROCK inhibitor Y-27632 is able to counteract the neurite growth inhibition of the MAP kinase (MAPK) inhibitor U0126 and that U0126 diminished the neurite accelerating effects of Y-27632. Such effects were now explored on a broader basis. We used the PKC inhibitor Bis1 to reduce neurite growth. Then, cells were co-exposed to eight different concentrations of the ROCK inhibitor Y-27632. A concentration of about 1 µM of the ROCK inhibitor brought the neurite area back to 100% (from a low start level of 60% by using the PKC inhibitor alone), and concentrations of 10 µM increased the neurite area to 130% of untreated controls (Fig. 9b). The potency of Y-27632 (half maximal effect at about 2 µM) was similar to its potency, when used alone (Fig.
Interestingly, Y-27632 also counteracted the growth-decreasing effects of colchicine and of rotenone; the concentration of the ROCK inhibitor required to show significant effects was always in a similar narrow concentration range, and the set of experiments yielded highly reproducible data (Fig. 9c-d).

In these experiments, the toxic effects of rotenone and colchicine were neutralized by a treatment that supposedly promotes neurite growth, but does not affect the binding of the toxicants to the primary targets (tubulin or mitochondrial complex I). These findings suggest that the adverse outcome of toxic compound exposure may not only depend on the assumed molecular initiating event, but also on many other factors. However, this would require detailed investigation in a more mechanistically-oriented study. There is in fact evidence from the literature that the ROCK pathway may affect microtubule stability (Gorovoy et al. 2005; Takesono et al. 2010). Some earlier data from other cellular systems suggest a rescuing effect of Y-27632 after treatment with rotenone (Sanchez et al. 2007) or with microtubule destabilizing compounds, such as colchicine or nocodazole (Keller et al. 2002; Niggli 2003; Zhang et al. 2001). These results from our test system corroborate such findings and indicate a good technical and mechanistic consistency of the test system. Intervention with toxicant effects would not only be helpful for clarifying the mode of action of DNT compounds, but it could also be interesting to explore potential rescue strategies after poisoning.

The practical application of toxicological in vitro test systems requires an extensive characterization of their performance characteristics. Especially the regulatory use of new animal-free assays has been strictly coupled to a formal validation procedure, as performed e.g. in Europe by the European Centre for Validation of Alternative Methods (ECVAM) (Corvi et al. 2012; Griesinger et al. 2010). Before such a time- and resource-consuming validation is performed, it is now common practice to pre-validate e.g. assay reproducibility and biological relevance. For high-throughput assays, evaluations similar to a formal pre-validation have been suggested as routine procedure to assess the usefulness and performance
of the assays (Judson et al, 2013). In both cases, this step of assay establishment requires a broad range of data to be generated, and multiple compounds to be used. This process usually goes far beyond an initial publication of a new test system (Hartung 2007; Hartung 2010; Leist et al. 2012). We have attempted here to provide such data and to provide a transparent and broad description of a test system that may be taken as example for similar approaches with other test systems.

**FIGURE LEGENDS**

**Fig. 1 Effect of Microtubule-depolymerising agents on neurite growth**

Cells were replated at day 2 (d2) into 96 well dishes, and toxicants were added 1 h or 3 days later. At 24 h after the start of the incubation with chemicals, cells were stained with calcein-AM and H-33342. The number of viable cells/field and the total neurite area/field were automatically detected and quantified on a high content screening microscope. a) Exposure scheme of LUHMES cells. Cells were either treated on d2 for 24 h and endpoints were assessed on d3 (developing cells) or cells were differentiated until d5, treated for 24 h and measured on d6 (mature cells). b) The upper row shows representative calcein images on the left side and the corresponding neurite area detected automatically by the imaging algorithm on the right side. The areas identified as neurites are marked in red; the nuclei of the cells detected by H-33342 staining are indicated by the circles. The lower row shows corresponding images of cells treated with 5 nM colchicine. Scale bar = 50 µm. c) Quantification of the neurite area of cells treated on d2 with nocodazole, vincristine or colchicine. d) Colchicine was added to LUHMES on d2. Resazurin reduction was measured 23 h later. Subsequently, calcein-AM and H-33342 staining was performed to quantify the number of viable cells and the neurite area. Blue dashed lines indicate the EC20 values for neurite area (1.9 nM) and viability (10 nM), the black solid line the EC50 of neurite area (4 nM). All data points are means ± SEM from three independent experiments. *p < 0.05 versus untreated control, #p < 0.05 versus viable cells at that concentration.

**Fig. 2 Comparison of compounds affecting neurite growth specifically or unspecifically**

LUHMES cells were treated as in Fig. 1a; all compounds were added on d2 and effects were measured 24 h later. All data points are means ± SEM from 3 independent experiments. a) Etoposide. b) Buthionine sulfoximine (BSO). c) Cycloheximide. d) Paraquat. *p < 0.05 versus untreated control, #p < 0.05 versus viable cells at that concentration.
**Fig. 3** Separation of specific neurite growth modulators from unspecific cytotoxicants

Cells were treated on d2 as displayed in Fig. 1a, and 24 h later neurite area and viability were automatically quantified. Compounds were tested at several concentrations, and their EC50 values for effects on neurite area and cell viability were determined by a non-linear regression sigmoidal concentration-response curve fit. The EC50 values of the neurite area were plotted against the EC50 values of general cell viability. First, a reference control group of 9 unspecific toxicants was measured (dots in grey, names are underlined). These comprised buthionine sulfoximine (BSO), carbonylcyanide-3-chlorophenylhydrazone (CCCP), 2,4-dinitrophenol (2,4-DNP), etoposide, bisbenzimide H (H-33352), potassium chromate (K$_2$CrO$_4$), tert-butyl hydroperoxide (tBuOOH), tween-20 and sodium dodecyl sulfate (SDS). The solid line indicates equal EC50 of viability and neurite area. The dashed line indicates an EC50 ratio of 4. Data for 40 compounds were classified according to this threshold value. Orange colour indicates substances classified to act unspecific on neurite growth: acrylamide, antimycin A, chlorpyrifos, chlorpyrifos oxon, cisplatin, cytochalasin, fipronil, haloperidol, honokiol, IPA-3, menadione, methamphetamine (METH), mevastatin, 1H-[1,2,4]oxadiazolo[4,3-α]quinoxalin-1-one (ODQ), okadaic acid, oligomycin, piericidin, protein tyrosine phosphatase inhibitor IV (PTP IV), puromycin, simvastatin and SP600125. Substances classified as specific neurite growth inhibitors (light blue) were: bisindolylmaleimide I (Bis1), brefeldin A, colchicine, cycloheximide, diquat, flavopiridol, methylmercury (II) chloride (MeHg), sodium orthovanadate (Na$_3$VO$_4$), narciclasine, nocodazole, paraquat, rotenone, U0126 and vincristine. Substances that increased the neurite area (dark blue) were: blebbistatin, HA-1077, H1152, thiazovivin and Y-27632. The 'neurite EC50' of these compounds was defined as the concentration resulting in a half-maximal increase of the neurite area. Data are means ± SD of 3 separate screens.

**Fig. 4** Reduction of neurite growth by rotenone and other respiratory chain inhibitors

LUHMES cells were treated as in Fig. 1a. a) Rotenone was added in fresh medium either 1 h after replating on d2 or on day 5. After 24 h incubation, viability and neurites were measured, and normalized to untreated controls. Viability curves of d3 and d6 were similar. Data are means ± SEM from 3 independent experiments. b) Representative images are shown, in
which the automatically detected neurite area (red) is overlaid over the calcein images. The position of the nuclei is marked by a blue outline. The width of the micrographs shown is 330 µm. Cells were incubated on d2 for 24 h with the indicated concentration of rotenone. c) Cells were treated on d2 with rotenone for 24 h. The data for viability and neurites are displayed for 4 independent experiments (dashed lines), each run in technical triplicates (individual error bars (± SD)). d) Antimycin A or oligomycin were added to LUHMES after replating for 24 h. Viability and neurite data are means from 2 (oligomycin) and 3 (antimycin A) independent experiments. All data points are means ± SEM from at least two independent experiments. *p < 0.05 versus untreated control, #p < 0.05 neurite area versus viable cells at that concentration.

**Fig. 5 Comparison of toxicant effects on d3 and d6**

Cells were replated at d2 and eleven compounds were tested with at least five different concentrations on d2 or on d5. After 23 h resazurin reduction was measured. Subsequently cells were stained with calcein-AM and 1 H-33342 for 30 min. The number of viable cells and the neurite area were automatically detected by Cellomics Array Scan. EC50 values of neurite area were plotted against the EC50s of viability. The dashed line indicates equivalent EC50 values of neurite area and viability. In cases of low cytotoxicity of compounds, the highest concentration measured was used as ‘EC50 viability’. All data are means of 3 independent experiments. a) Comparison of effects on viability and neurites on d3. b) Comparison of effects on viability and neurites on d6. c) Scatter plot of different EC50 ratios of the same compounds as in a/b. i) EC50 ratio of resazurin reduction of d6 to d3, ii) EC50 ratio of calcein positive cells to neurite area of d6, iii) EC50 ratio of neurite area of d6 to d3, iv) EC50 ratio of calcein positive cells to neurite area of d3.

**Fig. 6 Comparison of endpoint ratios (general viability vs. neurite area) of positive hits and unspecific toxicants at defined concentrations**

LUHMES cells were treated and measured as in Fig. 3. Each concentration for each compound is represented by one individual dot in the scatter plot. The effects of substances on viability are plotted against effects on the neurite area. The dashed line indicates equivalent values for neurite area and viability. Negative controls, such as aspirin and mannitol are marked by green dots. Black dots display values for unspecific compounds: buthionine sulfoximine (BSO), 2,4-dinitrophenol (2,4-DNP), etoposide, bisbenzimide H (H-33352), menadione, oligomycin, tert-butyl hydroperoxide (tBuOOH), tween-20, saponin and sodium dodecyl sulfate (SDS). Data from specific compounds are marked by blue dots.
bisindolylmaleimide I (Bis1), brefeldin A, colchicine, cycloheximide, MeHg, Na$_3$VO$_4$, nocodazole, paraquat, rotenone, U0126, and vincristine. The dashed grey box encircles dots which showed a reduction in neurite area of > 35 % and in viability of ≤ 20 %.

**Fig. 7** Comparison of the field based algorithm with a single cell based readout

LUHMES cells were treated as in Fig. 1a. Incubations were started on d2 and ended 24 h later to assess neurite area and number of viable cells per field. Cells were treated with substances (BFA = brefeldin A, Bis1 = bisindolylmaleimide I, CHX = cycloheximide, Flavo = flavopiridol, Men = menadione) at the concentrations indicated, and neurite area was assessed automatically (by the field-based Cellomics algorithm). The same images were re-analyzed manually. Every individual cell was scored for having a neurite extension that was longer than the corresponding cell soma diameter or not. Data from the field-based algorithm (y-axis) were compared with manually counted cells with neurites (x-axis).

**Fig. 8** Modulation of neurite outgrowth via the ROCK/RhoA pathway

At d2 cells were replated into 96 well plates and compounds were added at the concentrations indicated. At 24 h later, cells were stained with calcein-AM and 1 H-33342 for 30 min at 37°C. Neurite area and viability were automatically detected using Cellomics array scan. a) Thiazovivin. b) Narciclasine. c) HA-1077. d) Blebbistatin. e) Representative micrographs i) control, ii) narciclasine, iii) HA-1077, iv) blebbistatin. The width of each micrograph corresponds to 210 µm.

**Fig. 9** Antagonistic and additive effects of different neurite growth modifiers

LUHMES cells were treated as in Fig. 1a. Incubations were started on d2 and 24 h later, the neurite area and the number of viable cells per field were assessed. a) For all data points shown, 2 µM of bisindolylmaleimide I (Bis1) was added. In addition, different concentrations (0 – 12.5 µM) U0126 were added at the same time. The data for Bis1 alone are shown on the left part of the x-axis. b) Combination of ROCK-inhibitor Y-27632 plus 2 µM Bis1. c) Combination of ROCK-inhibitor Y-27632 plus 5 nM of Colchicine. d) Combination of ROCK-inhibitor Y-27632 plus 0.1 µM of Rotenone. All data are means ± SEM of 3 independent experiments. Data are normalized to untreated controls (ctrl). *p < 0.05 versus single compound treatment indicated on the left part of the x-axis.

Fig. S1 Toxicity curves of two positive compounds, vincristine and nocodazole, and of two negative compounds, etoposide and BSO.

Cells were replated at day 2 (d2) and compounds were added in dilution series in triplicates. 24h later cells were stained with 1 µM calcein-AM and 1 µg/ml H-33342 for 30 min at 37° C.

a) mean curve of vincristine toxicity of three biological replicates. b) mean curve of nocodazole toxicity of four biological replicates. c) single curves of viability and neurite area of three independent experiments of etoposide. d) single curves of viability and neurite area of three independent experiments of BSO.
**Fig. S2 Separation of specific neurite growth modulators (individual experiments) from unspecific cytotoxicants.**

Cells were treated on d2 as displayed in Fig. 1a, and 24 h later neurite area and viability were automatically quantified. Compounds were tested at several concentrations, and their EC50 values for effects on neurite area and cell viability were determined by a non-linear regression sigmoidal concentration-response curve fit, and EC50 values of neurite area were plotted against the determined EC50 values of cell viability. A reference control group of 9 unspecific toxicants comprised buthionine sulfoximine (BSO), carbonylcyanide-3-chlorophenylhydrazone (CCCP), 2,4-dinitrophenol (2,4-DNP), etoposide, bisbenzimide H (H-33352), potassium chromate (K2CrO4), tert-butyl hydroperoxide (tBuOOH), tween-20 and sodium dodecyl sulfate (SDS) (dots in grey, names are underlined). The solid line indicates an EC50 ratio of 1 for viability to neurite area. The dashed line indicates an EC50 ratio of 4.0 used as specificity cut-off here. Data for 40 compounds were classified according to this threshold value. Orange colour indicates substances classified to act unspecific on neurite growth: acrylamide, antimycin A, chlorpyrifos, chlorpyrifos oxon, cisplatin, cytochalasin, fipronil, haloperidol, honokiol, IPA-3, menadione, methamphetamine (METH), mevastatin, 1H-\[1,2,4\]oxadiazolo-\[4,3-a\]quinoxalin-1-one (ODQ), okadaic acid, oligomycin, piericidin, protein tyrosine phosphatase inhibitor IV (PTP IV), puromycin, simvastatin and SP600125. Light blue: substances classified as specific neurite growth inhibitors, EC50 values of three individual experiments are displayed: Bisindolylmaleimide I (Bis1), brefeldin A, colchicine, cycloheximide, diquat, flavopiridol, methylmercury (II) chloride (MeHg), sodium orthovanadate (Na3VO4), narciclasine, nodocazole, paraquat, rotenone, U0126 and vincristine. Dark blue: substances with an augmenting effect on neurite area: blebbistatin, HA-1077, H1152, thiazovivin and Y-27632. Neurite area EC50s of these compounds were determined as response halfway between the baseline (100%) and maximum. Grey dashed lines encircle the individual EC50 values determined for one compound.
**Fig. S3** EC50 values of neuronal precursor cells of neurite area and resazurin reduction compared to mature neurons.

Cells were replated at d2 and compounds were added to the culture medium in at least 5 distinct concentrations. For testing of mature neurons, cells were also replated at d2 and compounds were added in fresh medium at day 5 (d5). After 24 hours neurite area was quantified yielding concentration-response-curves. EC50 values were calculated, using the concentration-response-curves, as concentrations at 50% of neurite area were detected, respectively. All data are means of 3 to 4 independent experiments. Dotted lines mark equality of x-axis values to y-axis values.

**a)** Comparison of EC50 values of neurite area of developing (d3) and mature LUHMES cells (d6). The ratio of all d3 EC50 values to d6 is 11.43 ± 2.7. **b)** Comparison of EC50 values of resazurin reduction of d3 and d6 cells. The ratio of all d3 EC50 values to d6 is 0.74 ± 0.79.
Cells were replated at d2 and compounds were added to the culture medium in at least 5 distinct concentrations. For testing of mature neurons, cells were also replated at d2 and compounds were added in fresh medium at d5. After 24 hours resazurin reduction was quantified yielding concentration-response-curves. EC50 values were calculated, using the concentration-response-curves, as concentrations at 50% of resazurin reduction were detected, respectively. All data are means of 3 to 4 independent experiments. EC50 values were plotted against cytotoxicity data of non-neuronal cell lines derived from the Halle registry. Dotted lines mark the linear regression through the data points presented. **a)** and **b)** Comparison of EC50 values of resazurin reduction of d3 **a)** and d6 **b)** LUHMES cells with collected values of the Halle registry. The correlation of d3 to Halle registry is $R^2 = 0.87$ and of d6 to Halle registry is $R^2 = 0.85$. 

**Fig. S4** EC50 values of neuronal precursor cells and mature neurons of resazurin reduction compared to data from non-neuronal cell types.
